Institutional Review Board (IRB) approval was not required as this project does not constitute human subject research. The subject provided informed written consent for the publication of the study data.
Central Message

Spontaneous pulmonary torsion is a rare diagnosis that requires prompt intervention. The majority of cases require resection but select patients may benefit from detorsion and pleurodesis alone.

Central Picture Legend

Twisting of hilar structures with abnormal fissure orientation is suggestive of torsion.
Clinical Summary

A 56-year-old patient presented to his primary care provider (PCP) with 5 days of productive cough, shortness of breath, left-sided otalgia, and chills. The patient had a pre-syncopal event in the clinic, as he was hypoxic to 92% and significantly dyspneic at rest. He was evaluated in the emergency department where a chest x-ray revealed a right upper lobe infiltrate. Ceftriaxone and azithromycin were prescribed for the diagnosis of community-acquired pneumonia. Further testing was positive for Legionella pneumophila. He was discharged on hospital day 3 with oral antibiotics. The patient was readmitted later that week, with relatively unchanged imaging aside from a right-sided pleural effusion. He underwent thoracentesis which was non-revealing, and antibiotics were broadened to treat healthcare-acquired pneumonia. Institutional Review Board (IRB) approval was not required as this project does not constitute human subject research. The subject provided informed written consent for the publication of the study data.

The patient was evaluated by his PCP 2 weeks later. Persistent pulmonary symptoms prompted repeat imaging which demonstrated right hilar fullness with residual infiltrates and atelectasis. CT of the chest revealed the right middle pulmonary lobe to be positioned in the superomedial right hemithorax with occlusion of the right middle lobe bronchus (Central Picture). The right upper lobe was partially collapsed and located posteriorly, inferiorly, and medially with partial occlusion of the right upper lobe bronchus (Figure 1). The lobar arteries and veins were patent, but the right upper lobe pulmonary vein was extrinsically compressed. He was transferred to a higher level of care for further management.

Given the high likelihood of pulmonary ischemia in cases of torsion, the patient went to the operating room emergently for exploration. Through a right VATS, it was clear that the orientation of the right-sided lobes was grossly abnormal with the oblique and horizontal fissures
neither in their proper location nor orientation (Supplemental Video). The RLL basilar segment was noted to be incompletely fused to the lobe with an accessory fissure present. The inferior pulmonary ligament was visualized and noted to be angulated anteriorly. The lung was detorsed. The pulmonary parenchyma appeared healthy and viable. There were no signs of infarction and no masses or adenopathy that would raise suspicion for malignancy. A small nodule in the right upper lobe was biopsied; the final pathology was consistent with pneumonia. Betadine pleurodesis was performed and the operation was complete without any significant pulmonary resection. CT on post-operative day 1 demonstrated no recurrent torsion and the lung parenchyma appeared well-perfused. He was discharged home on postoperative day 3. The patient was evaluated in the clinic two weeks after surgery and did not have any recurrent pulmonary complaints.

Discussion

Pulmonary torsion is an uncommon condition that is most often associated with pulmonary malignancy, resection, or large-volume thoracentesis. The overall incidence is between 0.089% and 0.4%. Most commonly occurring after pulmonary resection, torsion can also occur following trauma, pneumonia with or without abscess, massive pulmonary effusion, in the presence of cancer, or spontaneously. Given its rarity, the literature associated with pulmonary torsion is sparing and limited mainly to case reports. The condition is notoriously difficult to diagnose, with up to an 18% rate of misdiagnosis. Vital sign abnormalities and symptoms are nonspecific and include tachycardia, fever, chest pain, or hypoxia. Radiologic findings of this condition include “the antler sign”, a result of the twisting of the hilar structures which leads to the unilateral abnormal appearance on axial imaging. Bronchoscopy can also reveal narrowing or inability to cannulate the bronchial orifice. Urgent intervention is required,
with most cases requiring resection due to prolonged ischemia, abscess, perforation, or malignancy. Failure to intervene carries a high risk of sepsis related to ongoing necrosis or recurrent infection in the affected lobe. Complications associated with detorsion include pulmonary vein thrombosis, ischemia-reperfusion injury, re-expansion pulmonary edema, or persistent air leak following laceration of the pulmonary parenchyma at a fixation point. Prior metanalysis has suggested that viable-appearing pulmonary tissue can be detorsed and not resected, with similar outcomes to patients who undergo detorsion and resection. Preventative measures for postoperative pulmonary torsion have been described in the literature and include creating a pleural flap, suturing or stapling of the lobes for fixation, or adhering the lobes to each other with materials such as BioGlue. There is a lack of consensus on the efficacy of these techniques, likely related to the relatively low incidence.

In our case, a patient with post-pneumonic torsion was diagnosed and operated on within 24 hours of transfer to our institution. After detorsion, the lung appeared to be well perfused, and resection was foregone. The patient recovered from his minimally invasive operation and has had no recurrent symptoms in the 2 years since surgery. Detorsion without resection may be used in select patients with spontaneous lung torsion without frank pulmonary infarct, abscess, or suspicion of malignancy.
